Abstract

The question of what items are stored in the lexicon is one that has drawn a lot of attention in the last few decades, and while the general consensus is that a lot more is stored than we previously realized, it is still largely unclear what factors drive storage. For example, some have argued that frequency drives storage, while others have posited that predictability drives storage. Further, it is unclear what the relationship between stored multi-word items and the representation of each individual word is. For example, it is possible that stored items fuse together, losing some amount of their internal structure. The present paper examines both of these questions by looking at the recognizability of the segment up in English V+up phrases. We find that the time it takes to recognize up decreases as frequency or predictability increases, but increases once again for the highest frequency or highest predictability items. Our results suggest that frequency and predictability both drive storage, and that stored items may lose some amount of their internal representation.

1. Introduction

When a listener hears the phrase *trick or treat*, do they process it compositionally, processing each word individually before combining them into a single parse? Or do they access a single holistically stored representation of the phrase from memory? This question of to what extent larger-than-word constructions can be stored and accessed holistically is one that psycholinguists have been interested in for quite some time (e.g., Bybee, 2002, 2003; Goldberg, 2003; Nooteboom et al., 2002; Stemberger and MacWhinney, 1986, 2004).

Throughout the years different theories have argued for different degrees of holistic storage, with two theories in particular dominating the field. On one hand, Chomskyan

theories (e.g., Chomsky, 1965; Pinker and Ullman, 2002) have proposed that only necessary items (e.g., items that can't be formed compositionally) are stored. On the other hand, usage-based theories (e.g., Bybee, 2003) have proposed that many items that could in principle be formed compositionally can be stored under certain usage-based conditions, such as frequency of use.

Traditional Chomskyan theories (e.g., Chomsky, 1965; Pinker and Ullman, 2002) have argued that processing multi-word phrases is completely compositional: each piece is accessed individually and then combined to form the larger meaning. Some exceptions are reserved for some idioms and other outliers, which can't be formed compositionally. More specifically, Chomskyan views of storage argue that whether an item is stored is determined purely by the degree of compositionality. According to these theories, if a multi-word expression can be composed from its parts then there is no need to holistically store the expression, and thus it is not stored holistically. For example since I don't know can be processed compositionally, it would be processed by composing a representation from each of the individual words, I, don't, and know. On the other hand, kicked the bucket would be stored holistically because there's very little relationship between the meaning of the individual words and the meaning of the expression (i.e., it's non-compositional).

Chomskyan theories of storage gained popularity partly because storage was thought to be a valuable resource that was taken up only by units that necessitated storage. This was perhaps influenced by the limited storage space of sophisticated computers at the time. In recent times, however, we've learned that the brain may have dramatically more space for storage than we had previously realized, with an upper bound of 10^{8432} bits (Wang et al., 2003). This is magnitudes larger than any current estimate of how much storage language requires.² Considering this, it might not come as a surprise that there has been a rise in support for usage-based theories of holistic storage over the past few decades (Kapatsinski and Radicke, 2009; Kapatsinski, 2018; Stemberger and MacWhinney, 1986, 2004; Morgan and Levy, 2016; Bybee and Scheibman, 1999; Bybee and Hopper, 2001; Bybee, 2002, 2003; Baayen et al., 2002; Ambridge, 2020; Zang et al., 2024).

Usage-based theories posit that more than just non-compositional items (e.g., multiword expressions) may be stored holistically in the lexicon, arguing that storage is driven by usage-based factors. For example, factors like frequency or predictability of the phrase may influence whether the phrase is stored holistically or not. According to these theories, in addition to idioms and non-compositional items, multi-word phrases such as *I don't know* may also be stored holistically if they are used frequently enough (e.g., Ambridge, 2020; Kapatsinski, 2018; Kapatsinski and Radicke, 2009; Hay, 2001; Lee and Kapatsinski, 2015; Arnon and Snider, 2010; Stemberger and MacWhinney, 1986, 2004; Morgan and Levy, 2016; Tomasello, 2005).

¹Some theories (e.g., Pinker and Ullman, 2002) have accepted that some very high-frequency items may be stored due to human memory, but these theories are much more conservative about what is stored compared to usage-based theories.

²Indeed, Mollica and Piantadosi (2019) estimated that, in terms of linguistic information, humans store only somewhere between one million and ten million bits of information, meaning that even their upper estimate is well within the capacity of the brain.

While it has become a dominant view in the field that at least some multi-word items are stored, it remains unclear what exactly the size of the units being stored is and, more so, what the factors driving storage are. Further, if multi-word representations are stored holistically, what are the consequences of this in terms of language processing?

1.1. Evidence of Holistic Storage

There is no shortage of evidence for holistic multi-word storage (e.g., Bybee and Scheibman, 1999; Stemberger and MacWhinney, 1986, 2004; Hay, 2001; Christiansen and Arnon, 2017; Zwitserlood, 2018), especially in the phonology literature. For example, Bybee and Scheibman (1999) demonstrated that the word don't is reduced to a larger extent in the phrase I don't know than in other phrases containing don't. In other words, the phrase I don't know seems to have its own mental representation. If it was the case that the representation of don't in I don't know was the same as the representation of don't in other contexts, then one would expect don't to be equally reduced in both cases (which is contrary to the finding in Bybee and Scheibman, 1999). Similarly, in Korean, certain consonants undergo tensification when they occur after the future marker -l. The rate of this tensification is higher in high-frequency phrases than low-frequency phrases, further suggesting that high-frequency phrases may be stored holistically (Yi, 2002).

In addition to the phonology literature, the Psycholinguistics literature has also provided an abundance of evidence for multi-word storage. For example, Siyanova-Chanturia et al. (2011) demonstrated that binomial phrases (e.g., cat and dog) are read faster in their more frequent ordering than in their less frequent ordering. Further, in a follow-up study, Morgan and Levy (2016) demonstrated that these ordering preferences for frequent binomials are not due to abstract ordering preferences (e.g., a preference for short words before long words), but are rather driven by experience with the specific binomial (i.e., how frequent each binomial ordering is), providing additional evidence that frequent phrases are stored holistically.

Similarly, Arnon and Snider (2010) demonstrated that frequent multi-word phrases are read faster than lower frequency multi-word phrases, even after accounting for the frequency of the individual words. This suggests that humans are sensitive to the frequencies of multi-word phrases. Further, in language production humans are also sensitive to the frequency of multi-word phrases. In a production study, Janssen and Barber (2012) found that participants produced frequent multi-word phrases faster than lower frequency phrases, even after taking into account the frequencies of the individual words.

Further, there is also evidence of multi-word storage from the learning literature (Siegelman and Arnon, 2015; Bannard and Matthews, 2008). For example, Siegelman and Arnon (2015) demonstrated that learning is facilitated by attending to the whole utterance, as opposed to attending to each individual word. Specifically, they used an artificial language paradigm to examine adult L2 learners' ability to learn grammatical gender. They found that adults learn grammatical gender better when they are presented with unsegmented utterances rather than segmented utterances. In other words, attending to the entire utterance, rather than learning to compose the utterance word-by-word, facilitated their learning. It seems plausible that if the entire utterance is being attended to, then participants may be learning (i.e., storing) the entire utterance initially. Further, storing

larger-than-word chunks may possibly be facilitating the learning of grammatical gender in their study.

1.2. What Drives Storage?

Despite the evidence of multi-word holistic storage, however, it is still largely unclear what factors drive storage. Humans seem to be sensitive to a variety of statistical information, including both frequency (e.g., Bybee and Scheibman, 1999; Maye and Gerken, 2000; Kapatsinski and Radicke, 2009; Lee and Kapatsinski, 2015) and predictability (e.g., Olejarczuk et al., 2018; Ramscar et al., 2013).

Traditionally, frequency has been assumed to be the driving factor behind multi-word storage. Indeed, most of the examples of storage given so far have been with respect to frequency. Perhaps the most famous series of studies demonstrating this were conducted by Bybee (Bybee and Scheibman, 1999; Bybee, 2003; Bybee and Hopper, 2001). In a series of studies, Bybee and colleagues demonstrated that a variety of words are reduced more in high-frequency contexts than low-frequency contexts (additionally see Kapatsinski, 2021, for further discussion of this). For example, in addition to the earlier examples, going to can be reduced in the frequent future marker, gonna, but not in the less frequent verb phrase construction describing motion (e.g., *gonna the store, Bybee, 2003). This mirrors patterns we see on a word-level (which for the most part must be stored). For example, the reduction of vowels to schwa in English is more advanced in high-frequency words than low-frequency words (Hooper, 1976; Bybee, 2003). In other words, for both words and phrases, sound reduction advances more quickly as a function of frequency (i.e., high frequency phrases and high frequency words are both more reduced than their lower frequency counterparts). While this is not surprising for words (which most theories posit have separate representations), it is surprising for phrases which don't necessarily have to be stored holistically.

On the other hand, predictability has not been directly examined much by the Psycholinguistics literature within the context of holistic multi-word storage (c.f. O'Donnell et al., 2009; Houghton and Morgan, 2023). One such study examining the role of predictability in holistic storage was Houghton and Morgan (2023). In their study, using the maze task³ (Boyce et al., 2020) the authors examined whether participants were slower to select the first noun in high-predictability compound nouns in locally implausible contexts (i.e., contexts where the first noun in the compound is implausible but where the second noun eliminates the implausibility; see the below sentences) relative to high-predictability compound nouns in locally plausible contexts.

- 1. **High Predictability Plausible:** Jimmy spread out the peanut butter.
- 2. **High Predictability Implausible:** Jimmy picked up the peanut butter.

Note that in the implausible condition, the second noun always eliminates the implausibility (i.e., spread out the peanut is implausible, but spread out the peanut butter is

³In the maze task, participants are presented a sentence word-by-word. For each word in the sentence, they are presented with the target word and an ungrammatical distractor. Upon selecting the target word, the next word in the sentence is presented along with yet another ungrammatical distractor. The key measure is how long it takes for participants to select the target word.

not). If high-predictability compound nouns are stored holistically, participants may be able to access the full compound noun upon encountering the first noun, thus overcoming the local implausibility effect (since the second noun in the compound always eliminates the implausibility). The authors found that the first noun in the compound nouns was selected slower in the implausible condition than in the plausible condition. Interestingly, this slowdown was roughly the same regardless of the predictability of the compound noun. That is, there was an increase in reaction time for selecting the first noun in the compound in the implausible condition (relative to the plausible condition) regardless of the predictability of the second noun in the compound noun. Their results suggest that either predictability doesn't drive the holistic storage of compound nouns or that it doesn't facilitate processing in this manner. However they noted that this may be a task effect, since they used the maze task as opposed to an eye-tracking task.

Despite the lack of direct evidence of predictability in the role of multi-word storage, however, predictability has been shown to play a crucial role in learning (Olejarczuk et al., 2018; Ramscar et al., 2013; Saffran et al., 1996). For example, Olejarczuk et al. (2018) demonstrated that when learning new phonetic categories, learners don't just pay attention to co-occurrence rates, but actively try to predict upcoming sounds, suggesting that the learning of phonetic categories is also driven by prediction (i.e., the predictability of a given sound within a context). Further, in learning new words, Ramscar et al. (2013) demonstrated that children are sensitive to how predictable a cue is of an outcome (e.g., a high-frequency cue will be ignored if it isn't predictive of a specific outcome). Additionally, word-segmentation (i.e., learning which segments in an utterance are words) is also highly sensitive to predictability (Saffran et al., 1996). In their classic paper, Saffran et al. (1996) demonstrated that children keep track of transitional probabilities – a measurement of predictability – to segment the speech stream. While these are studies examining learning, not storage, the units that we learn may likely be the units we store. If predictability drives what we learn, it may also drive what we store.

Thus, the current literature presents strong evidence for the role of frequency in the storage of multi-word phrases, as well as suggests the possibility of a further influence of predictability. However, it remains unclear to what extent each of these factors drives storage and whether they interact at all with each other.

1.3. Representation of Stored Units

Given the evidence that a lot more may be stored than previously thought, another important question to consider is what the internal representations of these units is. Specifically, do the stored units maintain their own internal representation with respect to their component parts? For example, it is possible that the representation of high-frequency phrases, such as $pick\ up$, retains the representations of the component parts $pick\ and\ up$. On the other hand, it is possible that the phrase lacks internal representation of the component parts, either because it was lost over time or because it was not learned to begin with.

Indeed, there seems to be some evidence that multi-word phrases may not have a fully intact internal structure with respect to their component parts. For example, Kapatsinski and Radicke (2009) demonstrated that in high frequency V+up constructions, it is

harder to recognize the segment up (with respect to medium-frequency V+up constructions). This suggests that those items may have a holistic representation that has lost some of its internal structure. In their study, participants were given different auditory sentences and tasked with pressing a button immediately if they heard the segment up. Interestingly, they found that recognizability of up follows a U-shaped pattern with respect to the frequency of the phrase. That is, participants were slow to recognize up in low frequency phrasal verbs, but for medium-high frequency phrasal verbs they were quicker to recognize up. However, upon reaching the highest frequency words participants once again grew slower to recognize up (See Figure 1). Though it's important to note that the original paper does not take into account predictability. It's unclear how to account for the increase in recognition time for the highest frequency items if there is no loss of internal representation of those items.

A visualization of what a stored representation with and without internal structure may look like is presented in Figure 2. The left tree represents the phrase $pick\ up$ stored with its internal structure still intact, whereas the right tree represents $pick\ up$ stored without internal structure. Note that both trees are examples of a holistically stored representation. The key difference is whether the internal structure remains intact in the holistic representation. The results from Kapatsinski and Radicke (2009) suggest that for high-frequency verb+up collocations, their representation may be more similar to the tree on the right, since participants were slower to recognize up. We will revisit this point in the discussion section in more detail.

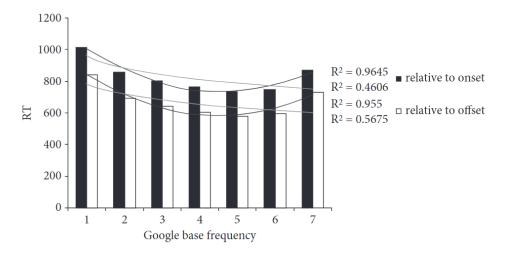

Figure 1: The U-shaped effect of the frequency of verb+up constructions on the speed with which up is detected, reproduced from Kapatsinski and Radicke (2009).

It's worth noting that in the case of phrasal verbs like *pick up*, it can't be the case that the entire internal representation is lost because it is possible to syntactically alternate it (e.g., *pick up the cup* vs *pick the cup up*). However, it is possible that semantic or lemma information is lost in the holistic representation. That is, it is possible that syntactic and/or morphological information may be preserved even if semantic or lemma

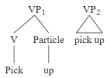

Figure 2: A diagram of two ways the word $pick\ up$ could be stored. The left tree demonstrates a stored representation of $pick\ up$, where the internal structure is still intact. The right tree demonstrates a holistically stored unit, where there is a loss of internal structure. Note that both of these are stored structures, as opposed to a compositional representation of $pick\ up$ which would be comprised of the individual representations pick and up.

information is lost. In other words, loss of internal representation may happen at different levels as opposed to being an all-or-nothing process.

Additionally, there is also evidence from the word-recognition literature that some stored words may also lose some of their internal structure as well. For example, Healy (1976) examined participants' ability to recognize letters in various words. He found that people were worse at recognizing the letter t in the than in other lower frequency words, which suggests that even words can develop a representation separate from their component pieces (in this case, the component parts being letters instead of words). If it is the case that the is recognized as a composition of its parts, then one would expect participants to be equally good at recognizing the letter t in the as they are in other words. Interestingly, Kapatsinski and Radicke (2009) suggested that one explanation is that people don't fixate as long on high-frequency and function words, of which the is both. However, they found similar results with auditory stimuli, suggesting that the results that Healy (1976) found may not be due to participants skipping high-frequency words in reading.

On the other hand, it is possible, as was put forth by both Kapatsinski and Radicke (2009) and Healy (1976), that during processing the holistic representations compete with the representations of the individual parts for recognition. That is, there is a lot of evidence that different mental representations compete for recognition (Oppenheim and Balatsou, 2019) and are only activated when they receive sufficiently more activation than their competitors (McClelland and Rumelhart, 1981). For example, in picture-naming tasks in which participants are tasked with naming a picture while confronted with a distractor word, participants are generally slower to produce the intended word when the distractor word is semantically related to the picture (Starreveld and La Heij, 1995; Schriefers et al., 1990; McClelland and Rumelhart, 1981). It is possible that the delay in reaction time for up may be a consequence of competition rather than a loss of internal representation. In other words, for high-frequency/high-predictability phrases that are holistically stored, the increase in reaction time may be explained by competition between the holistically stored representation and the word-level representations. In the present study, we examine both phrasal verbs, such as pick up, which can syntactically alternate (pick the cup up vs pick up the cup) and non-phrasal verbs, such as stir up, (??stir the controversy up). Since phrasal verbs can syntactically alternate, it is possible that they are all stored holistically regardless of frequency. In other words, all of the phrasal verbs

may be stored, but only the most frequent and/or most predictable non-phrasal verbs should be stored. Thus, by examining both classes of multi-word items, we should be able to gain insight into whether competition alone can account for previous results. Specifically, if the results are due to competition between the component words and the holistic representation (without a loss of internal representation), then we should see a slowdown for all of the phrasal verbs, regardless of frequency, and only see a slowdown for the highest frequency and/or most predictable non-phrasal verbs. However, if the results are due to a lack of internal representation, we should only see a slowdown for the most frequent and/or most predictable phrases, regardless of whether they are phrasal verbs or not. We will elaborate on this point in the discussion.

1.4. Present Study

The present study examines the factors that drive storage and the representations of stored items by extending Kapatsinski and Radicke (2009) to look at the effects of both frequency, predictability, and their interaction on the processing of V+up phrases. Similar to Kapatsinski and Radicke (2009), participants are tasked with pressing a button once they hear the segment up (which in our study occurs either as a particle within verb phrases, e.g., pick up, or part of a word, e.g., puppet), but in our case the stimuli varied in frequency, predictability, and whether they were a phrasal verb or not. Since both frequency and predictability effects are rather robust in the literature, we should at the very least see a negative correlation between frequency/predictability and recognition time (up to perhaps a certain point, where recognition time may increase). Further, if predictability is not a driving factor of storage, we should see an increase in recognition times for only the most frequent phrases. On the other hand, if predictability does drive storage, we may see an increase in reaction time for both frequent and predictable phrases. This increase in recognition time may simply be a consequence of competition between the representations of holistically stored phrases and the representations of their component words, or may also reflect a lack of internal structure depending on whether we see similar effects for both phrasal verbs and non-phrasal verbs.

2. Methods

2.1. Participants

Participants were recruited through the University of California, Davis Linguistics/Psychology Human Subjects Pool. 350 people participated in this study and were compensated in the form of course credit. All participants self-reported being native English speakers. Additionally, 44 participants were excluded due to an accuracy score below our threshold of 70%, leaving a total of 306 participants for the data analysis.

2.2. Materials

We searched the Google n-grams corpus (Lin et al., 2012) for the most predictable and the highest frequency phrases that matched our criteria of containing a verb immediately followed by the word up. We operationalized predictability as the odds ratio of the probability of up occurring immediately after the verb to the probability of any other word occurring (Equation 1).

$$\frac{\operatorname{count}(\operatorname{Verb} + up)}{\operatorname{count}(\operatorname{Verb}) - \operatorname{count}(\operatorname{Verb} + up)} \tag{1}$$

In non-mathematical terms, the above equation quantifies how likely up is to follow after the verb relative to every other word that could follow. For example, the odds ratio of $pick\ up$ would be the number of times the entire verb phrase occurs $-pick\ up$ — divided by the number of times the verb -pick — occurs without up following it.

For the purposes of the present study, we gathered a variety of phrases that varied in both their predictability and frequency and their combination. In order to do this, we extracted the 50 most frequent $\operatorname{Verb}+up$ items and the 50 most predictable ones. Next, we selected 100 more by randomly sampling from the remaining items. In order to ensure stable predictability estimates we eliminated words that a college-aged speaker wouldn't have heard more than 10 times. We then visually inspected the data to confirm that our data spanned across both the frequency and predictability continuum. This distribution is presented in Figure 3 below.

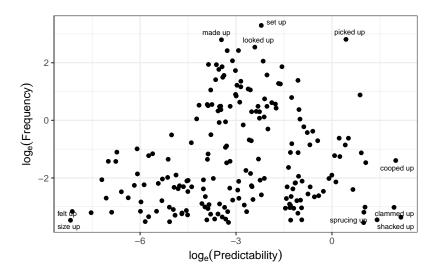

Figure 3: log-predictability by log-frequency (per million) plot of our items.

- (1) a. The controversy stirred up a heated debate.
 - b. ??The controversy stirred a heated debate up.

Phrasal verbs show a syntactic alternation that is not present in all verb+up collocations (e.g., picked the peanut up is fine, but stirred a heated debate up is weird at best).

⁴Levy et al. (2012) extrapolated that the average college-aged speaker has heard about 350 million words in their lifetime. Thus we excluded items that had a frequency smaller than 10 per 350 million.

It is possible that due to this syntactic alternation, phrasal verbs may be stored regardless of frequency/predictability. This is because in order to properly use phrasal verbs, a speaker must be aware of the syntactic alternation, which can't simply be predicted compositionally (e.g., some V+up phrases are phrasal verbs, while other V+up phrases are not phrasal verbs). Thus, we additionally coded our stimuli for whether they were phrasal verbs or not. This coding was done based on whether they could syntactically alternate between having the noun within the verb phrase and having the noun immediately after the verb phrase. For example, since both pick the cat up and pick up the cat are grammatical, pick up was classified as a phrasal verb. Each item was checked by two of the authors. Disagreement was easily resolved by discussion and an agreement was reached for every item.

We also searched the same corpus for words that contained the segment up (e.g., cup-cake). In order to gather a subset of words that roughly matches the frequency range of our experimental stimuli, we extracted the 50 most frequent words, then sampled from the rest of the dataset to gather an additional 100 words. These 350 items together comprise our stimuli.

For each item, we constructed two sentences: one sentence which contained up, and one sentence that was identical except that it didn't include the segment up. For words, the entire word was replaced. For phrases, up was simply deleted if possible (e.g., clean up replaced with clean). If this resulted in an awkward sentence, the entire phrase was replaced. An example is given below.

- (2) a. He picked up the phone and answered the call.
 - b. He grabbed the phone and answered the call.

In summary, our stimuli were comprised of 200 Verb+up phrases that varied in both frequency and predictability, 150 words that contained up, and 350 filler sentences which were matched with our experimental sentences with the exception of having up replaced.

After creating the sentences, a native English speaker then recorded each sentence in a random order to minimize any list effect. We subsequently equalized the amplitude such that every sentence was roughly the same loudness.

2.3. Procedure

Participants were presented with audio sentences via Pavlovia (https://pavlovia.org/), a website for presenting PsychoPy experiments (Peirce et al., 2019). Each participant was presented with 3 practice trials and then 350 sentences. While we had a total of 700 sentences, participants didn't see both the filler and experimental sentence for the same item, thus they only saw half of the stimuli. The order of the sentences was random and exactly half of the sentences contained the target segment (to avoid biasing the participants towards a specific response). Participants were instructed to press a key as soon as they heard the segment up, or to press a separate key at the end of the sentence if they did not hear the target segment in the sentence. We then recorded their reaction time of the button press. The experiment took approximately 40 minutes.

2.4. Analysis

The data⁵ was analyzed using General Additive Mixed models, as implemented in the mgcv package (Wood, 2011) within the R programming environment (R Core Team, 2023). General Additive Mixed Models are models that allow us to model our outcome variable as a combination of the predictors. GAMMs differ from generalized linear regression models in that they allow the predictors to be modeled as non-linear functions, similar to polynomial regression. Specifically, in a Generalized Additive Mixed Model, beta-coefficients are replaced with a smooth function, which is a combination of splines. The more splines that we include, the more wiggly our line will be. In order to avoid overfitting, GAMMs also include a penalty term, λ , which can be modified to penalize more wiggly lines that aren't justified by the data. While the predictors are allowed to vary non-linearly, the linking function in our case was linear (i.e., response time varied linearly with the spline functions).

For all of our models, the dependent variable was the time it took for participants to react to the onset of the target segment in experimental sentences/sentences containing up (i.e., the time it took participants to press the button after hearing up). For the first model, the predictors were the interaction between log-predictability and log-frequency, which was allowed to vary non-linearly, and duration of the segment, which was not allowed to vary non-linearly. Additionally, we also included random intercepts for participant, trial, and item, as well as random by-participant slopes for predictability, frequency, their interaction, and trial. All our random-effects were allowed to be wiggly (non-linear). Our model formula is included below in Equation 2:

$$log(RT) \sim ti(Predictability, Frequency) + Duration + s(participant, bs = `re') + s(Item, bs = `re') \\ + s(trial, bs = `re') + s(Predictability, Frequency, participant, bs = `re')$$
 (2)

We also ran an additional analysis similar to the first model, but allowing the interaction to vary for phrasal vs non-phrasal verbs. Specifically, the model is identical to the first model with the exception that the effect of the interaction term was allowed to be different for phrasal verbs and non-phrasal verbs. This was done in order to examine whether the effect of frequency and predictability was different for phrasal verbs versus non-phrasal verbs. See Equation 3:

$$log(RT) \sim ti(Predictability, Frequency, by = PhrasalVerb) + Duration + s(participant, bs = `re') \\ + s(Item, bs = `re') + s(trial, bs = `re') + s(Predictability, Frequency, participant, bs = `re') \\ (3)$$

Additionally, we ran a Generalized Additive Model with frequency, predictability, and the interaction between frequency and predictability as fixed-effects that could vary non-linearly, and duration of the segment as a fixed-effect that could not vary non-linearly.

⁵The stimuli, data, and analyses scripts can all be found freely available here: https://github.com/znhoughton/Recognizability-Experiment

The random-effects structure for this model was identical to the previous two models. The model syntax is included below in Equation 4:

$$log(RT) \sim s(Predictability) + s(Frequency) + ti(Predictability, Frequency) + Duration \\ + s(participant, bs = `re') + s(Item, bs = `re') + s(trial, bs = `re') \\ + s(Predictability, Frequency, Trial, Participant, bs = `re')$$

$$(4)$$

Finally, we replicated the analyses from Kapatsinski and Radicke (2009) using two Bayesian quadratic regression models (implemented in *brms*; Bürkner, 2017), one which only included frequency, and one which only included predictability. For the frequency model, the fixed-effects were log-frequency and log-frequency², along with duration. The model also included random intercepts for participant and item, and random slopes for log-frequency by participant, duration by participant, and log-frequency² by participant.

The quadratic regression with predictability was identical to the quadratic regression with frequency, except that log-frequency was replaced with log-predictability, and log-frequency² was replaced with log-predictability². The random-effects were modeled without correlations between them for both models (this was done to allow the model to run faster, since we collected a large amount of data).

The model syntax for both models is included below in Equation 5 and Equation 6:

$$log(RT) \sim log(Frequency) + Duration + log(Frequency^{2}) + (1 + log(Frequency) + log(Frequency^{2}) + Duration||Participant) + (1||Item)$$

$$(5)$$

$$\begin{split} log(RT) \sim log(Predictability) + Duration + log(Predictability^2) \\ + (1 + log(Predictability) + log(Predictability^2) + Duration || Participant) + (1 || Item) \\ (6) \end{split}$$

3. Results

First, we present the results of our generalized additive models. The result of our first generalized additive model (Table 1; Equation 2) suggested no significant interaction effect between frequency and predictability. A visualization is provided below in Figure 4.6

Further, the results of of our second generalized additive model (Table 2; Equation 3) suggested that even after accounting for whether the verb phrase was a phrasal verb

 $^{^{6}}$ We also examined the interaction between frequency and predictability on accuracy (whether they correctly responded to whether up was present in the sentence) and similarly found no significant effect.

or not, there was no significant interaction effect. A visualization is provided below in Figure 5.

Finally, our third generalized additive model (Table 3; Equation 4) suggested that there was a significant main-effect of predictability. To summarize the results of our generalized additive models, we found no interaction effect between frequency and predictability, no main effect of frequency, but we do find a significant main effect of predictability. A visualization is provided below in Figure 6.

A visualization of Table 1 and Table 2 are presented in Figure 4 and Figure 5.

Given these results, we ran a follow-up Bayesian quadratic regression model to further examine the effects of frequency and predictability on recognition times. Since the

The brightness of the coloration denotes the strength of the effect at the point in the graph. Brighter colors denote longer reaction times.

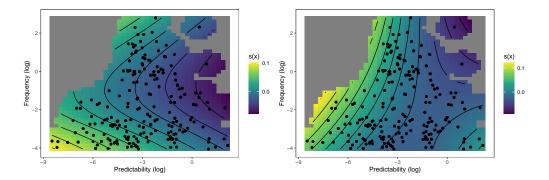

Figure 5: Plot of the interaction effect between predictability and frequency of our GAM model containing the interaction between frequency and predictability for phrasal vs nonphrasal verbs. Brighter colors denote longer reaction times. The left graph is the predicted effect for phrasal verbs (e.g., pick up), the right graph is the predicted effect for non-phrasal verbs (e.g., walk up).

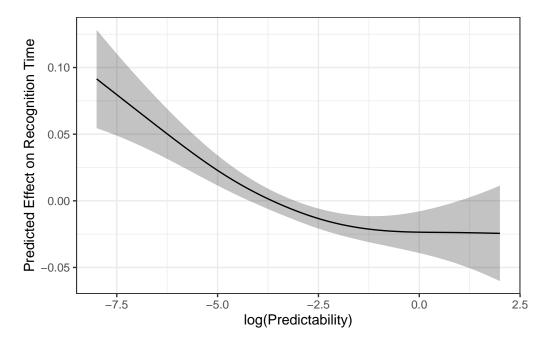

Figure 6: Plot of our GAM model's predicted effect of log(predictability) on recognition time.

Generalized Additive Model suggested that there was no significant interaction between frequency and predictability, we left out the interaction term from the regression model. Similar to the above Bayesian models, we also modeled the random-effects without correlations between them. Equation 7 below presents the full model syntax:

$$log(RT) \sim log(Frequency) + log(Predictability) + Duration + log(Frequency^2) + log(Predictability^2) + (1 + log(Frequency) + log(Predictability) + log(Frequency^2) + log(Predictability^2) + Duration||Participant) + (1||Item)$$

$$(7)$$

The results of this model are presented below in Table 4 and visualized in Figure 8. Following Houghton et al. (2023), in some cases where the confidence interval crosses zero, we also report the percentage of posterior samples greater than or less than zero. For the current model, although the confidence intervals for both quadratic terms crossed zero, nearly 97% of the posterior samples for predictability² were greater than zero, and nearly 93% of the posterior samples for frequency² were greater than zero. A plot of the posterior distribution for each coefficient is presented in Figure 7. The results suggest a U-shaped effect of both frequency and predictability on recognition times. In other words, participants recognized up faster as frequency or predictability increased, except for the most frequent or most predictable items, where participants were slower to recognize up.

Finally Table 5 and Table 6 present the results for the quadratic regression models including only frequency and frequency as well as the quadratic regression model in-

4. Discussion

The present study examined the effects of frequency and predictability on the recognizability of the particle up in English phrasal verbs. We found a U-shaped effect for both frequency and predictability on recognizability: as frequency/predictability increased, people were faster at recognizing up, until reaching the highest frequency/most predictable items, where people were slower. These results suggest that the most predictable and/or highest frequency items have a lack of internal structure. We also found no meaningful differences between phrasal verbs (e.g., $pick\ up$) and non-phrasal verbs (e.g., $siir\ up$), suggesting that this effect is driven primarily by the statistical distribution of the input as opposed to syntactic properties.

First, our results suggest that both frequency and predictability drive storage, as we see an increase in recognition times for the highest frequency and highest predictability items. It is unclear how this result can arise without storage of the entire verb phrase, since in order for up to be harder to recognize in some contexts than in other contexts, it must have a separate representation.

Our results also demonstrate that as frequency or predictability increases, recognition time decreases until reaching the highest frequency/predictability items where there is an increase in recognition time. One possible interpretation of our results is that the slowdown is due to competition between different levels (e.g., competition between the representation for a holistically stored phrase and the separate representations for its component parts). Specifically, for medium-high frequency items, since they are likely not stored, there is no holistically stored representation to compete, hence the decrease in recognition times. However, for the highest frequency items, they may have a holistically stored representation which may compete with, and even inhibit, the representations of the component parts, thus leading to an increase in recognition times.

This replicates previous findings that found competition between different levels during processing (e.g., Kapatsinski and Radicke, 2009; Healy, 1976, 1994; Minkoff and Raney, 2000). For example, as stated earlier, Healy (1976) found that people make more

letter-detection errors in high-frequency words (e.g., the) than in lower frequency words. Further, Minkoff and Raney (2000) found that letters are more difficult to detect in high-frequency nouns than in low-frequency nouns. Taken altogether, these results suggest that recognizing words or holistically stored phrases does not necessarily require processing them through the representations of the component parts, and in fact, processing the holistically stored phrases may make it even more difficult (via inhibition) to process the representations of the component parts.

On the other hand, rather then being driven by competition, it's possible that listeners are simply able to process the meaning of frequent phrases fast enough that they don't wait to hear the entire phrase. For example, it's possible that for high-frequency and high-predictability items, when accessing the first word, e.g., pick, the listener accesses the representation of the entire phrase (e.g., pick up) immediately, before even hearing up, and then continues on to process the next words (skipping over up). Since the task is to respond when they hear up, the delay in reaction time may be because they're not accessing the phonological representation of up. Instead, they may access the semantic representation of the phrase without initially accessing the phonological representation of up. They may then be recovering the phonological representation from the semantic representation of the phrase, causing a delay in recognition time. Indeed, this possibility was suggested by Healy (1976), who suggested that in reading once people process the meaning of a word, they move on to the next word regardless of whether they have processed each individual letter. However, while this is plausible in reading, it seems much less likely in speech processing. Since listeners receive auditory signal in a continuous stream, listeners don't have an option analogous to skipping to the next word in reading. Our results are instead more compatible with a race model with inhibition, such as the TRACE model (McClelland et al., 1984). Specifically, it seems plausible that rather than skipping the word, it is being inhibited by the holistic representation. That is, upon processing pick up, the representations of the component parts pick and up are inhibited.

A third possibility, however, is that the holistic phrase's internal structure may not be fully intact. Indeed, this interpretation seems quite likely given that we see a U-shaped effect in both phrasal (e.g., pick up) and non-phrasal verbs (e.g., stir up). That is, phrasal verbs have a syntactic alternation that may lead to all of them being stored, regardless of whether they are frequent/predictable or not. If the increase in reaction time is simply due to competition between the holistically stored representation and the individual word-level representations, then if all phrasal verbs are stored we would expect that all of the phrasal verbs were slower. However, while loss of internal representation indicates storage, storage does not necessitate a loss of internal representation. It is the combination of storage and usage that leads to loss of internal representation. Thus, our results seem most compatible with a combination of a lack of internal representation in frequent/predictable items along with competition (inhibition of the component words upon processing the holistic representation).

For example, perhaps the internal structure for the high-frequency and high-predictability items was never learned to begin with. Children are experts at statistical learning and use transitional probabilities to divide the continuous speech stream (Saffran et al., 1996) and high predictability phrases in the present study, by definition,

have higher transitional probabilities between words. Thus if children are relying on transitional probabilities to separate speech into individual words, the individual words in the most predictable phrases may not be separated out of the speech stream initially.

Further, many high-frequency (e.g., set up) and high-predictability (e.g., conjure up) phrases have semantically vague relationships that might make it difficult to split them up on a semantic basis. It seems plausible then that maybe these phrases weren't learned as being composed of individual words initially and thus the internal structure for the holistically stored items may not have been learned. The example, trick or treat, is a prime example of a phrase that does not seem to have a clear semantic relationship between the phrase and its component parts.

In summary, we demonstrate that both frequency and predictability drive the holistic storage of phrasal verbs, and these holistically stored items may compete with their component parts during lexical access. Further, while future work is needed to fully rule-out a simple competition account, we argue that our results demonstrate a lack of internal structure for frequent/predictable multi-word phrases.

5. Acknowledgements

The authors would like to thank Dingyi (Penny) Pan, a graduate student in Linguistics, for reading and offering comments on a draft of this paper. The authors would also like to thank Vsevolod Kapatsinski and Zara Harmon for providing interesting discussion about the nature of competition in processing.
